ABSTRACT
For curbing recent COVID-19 outbreaks, suppression and mitigation are two typical intervention strategies. Both strategies have their merits and limitations, and hardly achieve an optimal balance between healthcare demand and economic protection. This paper designed a model to attempt to access effectiveness of multiple rolling interventions for controlling COVID-19 outbreaks in London and the UK. Our model assumed that each intervention has equivalent effect on the reproduction number $R$ across countries and over time; where its intensity was simply presented by average number contacts with susceptible individuals as infectious individuals. We considered two key features: direct link between Exposed populations and Recovered populations, and actual healthcare demand by separating mild, severe and critical cases. We combined the calibrated model with data on the cases of COVID-19 in London and non-London regions in the UK during February 2020 and March 2020 to estimate the number and distribution of infections, growth of deaths, and healthcare demand using multiple interventions. The results show that one optimal strategy was to take suppression with high intensity in London from 23rd March for 100 days, and 3 weeks rolling intervention between high intensity and moderate intensity in non-London regions. In this case, the total infections and deaths in the UK would be limited to 9.3 million and 143 thousand; the peak time of healthcare demand was due to the 96th day (May 11th), where it needs hospital beds for 68.9 thousand severe and critical cases. This strategy potentially reduces the overall infections and deaths, and delay and reduce peak healthcare demand.

1 INTRODUCTION
Infectious diseases (ID), also known as transmissible diseases, are widely considered as serious threats to global public health and economics [1]. Recent ongoing global outbreaks of coronavirus disease 2019 (COVID-19) has spread to at least 146 countries, and killed over 640 thousands people in the world by 25th July 2020 [2]. In order to give an accurate prediction of outbreaks, many researchers have been working in traditional ID propagation models [3-7] like SIR, SEIR, et.al, for understanding COVID-19 transmission with human mobility and predicting outbreak process of epidemics. Also, as realizing a long period of this battle against COVID-19, many of them focus on studies of intervention strategies [8-10] that can balance a trade-off between limited human mobility and potential economic loss in COVID-19 control. It poses an important research area that explores how and when to take what level of interventions in light of multiple natures and capabilities of countries.

Compartmental models have a long history of being applied in epidemiology. SIR (Susceptible–Infectious–Recovered) [3] and SEIR (Susceptible –Exposure–Infectious–Recovered) [4] are two popular approaches to simulate and predict how infectious disease is transmitted from human to human. These two models have defined several variables that represent the number of people in each compartment at a particular time. As implied by the variable
function of time, these models are dynamic to reflect the changes and fluctuations of these numbers in each compartment over time. For COVID-19 control in Wuhan, Zhong, et al. [11] introduced a modified SEIR model in prediction of the epidemics trend of COVID-19 in China, where the results showed that under strong suppression of “lockdown Hubei”, the epidemic of COVID-19 in China would achieve peak by late February and gradually decline by the end of April 2020. Some other extended models [8] [12] were proposed for predicting the epidemics of COVID-19 in Wuhan and give some similar forecasts. While above methods demonstrate good performance in prediction of COVID-19 outbreak by taking strong public intervention (suppression) [13] that aims to reverse epidemic growth, one important challenge is that taking suppression strategy only is to treat disease controls as single-objective optimisation of reducing the overall infectious populations as soon as possible, and require strategic consistency in the long term. In real-world, taking public health intervention strategies is a multi-objective optimisation problem including minimizing economic loss and society impacts. Many countries have implemented multiple intervention strategies, like enhanced surveillance and isolation to affected individuals in Singapore [14], four-stage response plan of the UK [15-16], mitigation approaches [13] and even multiple interventions taken in many EU countries [17-21]. Due to the fact that standalone intervention strategy has apparent merits and limitations, it is necessary to study the feasibility of intervention strategies to certain country in light of its multiple natures and capabilities.

This paper conducts a feasibility study that analyses and compares mitigation and suppression intervention strategies for controlling COVID-19 outbreaks in the UK. Taking Wuhan as a case using data from [11] for initial simulation analysis, we found the performance of taking different intervention strategies [16] [22]:

a) No interventions: the peak of daily infections would be up to 1.8 million, but will be completed in 150 days. The epidemics lasts a relatively shorter period of 130 - 140 days, but lead to more death.

b) Suppression intervention from the 32nd day: the peak of daily infections greatly reduced to 33 thousand, but it had to be followed at least 150 days. Nearly 3 months suppression may potentially lead to economic loss even crisis. c). Mitigation intervention from the 32nd day: the peak of daily infectious populations increased to 114 thousand, but the period of maintenance extended to 250 days. It implied there would be growing death but less economic loss compared to suppression. d). Hybrid interventions every 2 weeks: the epidemics of COVID-19 appeared a long-term multimodal trend where the peaks of daily infectious populations were within a range of 34-42 thousand. This might lead to less daily critical cases and offer more time to hospital for releasing their resources.

Above analysis demonstrates the complexity of controlling COVID-19 outbreaks that how and when to take what level of interventions. Thus, we proposed a mathematical model: SEMCR to study this problem. The model extended traditional SEIR (Susceptible-Exposed-Infectious-Recovered) model [3-4] by adding one important fact: there has been a direct link between Exposed and Recovered population. Then, it defined parameters to classify two stages of COVID control: active contain by isolation of cases and contacts, passive contain by suppression or mitigation. The model was fitted and evaluated with public dataset containing daily number of confirmed active cases including Wuhan, London, Hubei province and the UK during January, 2020 and March 2020. For accessing impacts of each intervention, we design and set up experimental protocols for comparison and exploration, highlighting following contributions:

- In the UK, one optimal strategy was to take suppression with very high intensity in London from 23rd March for 100 days, and 3 weeks rolling intervention between very high intensity and high intensity in non-London regions. In this scenario, the total infections and deaths in the UK were limited to 9.3 million and 143 thousand; the peak time of healthcare demand was due to the 96th day (May 11th), where it needs hospital beds for 68.9 thousand severe and critical cases.

- To release rolling intervention intensity to moderate level and simultaneously implement them in all regions of the UK, the outbreak would not end in 1 year and distribute a multi-modal mode, where the total infections and deaths in the UK possibly reached to 23.3 million and 971 thousand.

- Our results show that taking rolling intervention is probably an optimal strategy to effectively and efficiently control COVID-19 outbreaks in the UK. As large difference of population density and social distancing between London and non-London regions in the UK, it is better to take consistent suppression in London for 100 days and rolling intervention in other regions. This strategy would potentially reduce the overall infections and deaths, and delay and reduce peak healthcare demand.

The remainder of this paper is arranged as follows. Section 2 introduces the model. In the Section 3, the materials and implementation of experiment are reported. Section 4 provides detailed experimental evaluation and discussion. The conclusion and future directions are given in Section 5.

2 METHODOLOGY

2.1 Problem formulation of COVID-19 outbreak

We implemented a modified SEIR model to account for a dynamic Susceptible [S], Exposed [E] (infected but asymptomatic), Infectious [I] (infected and symptomatic) and Recovered [R] or Dead [D] population’s state. For estimating healthcare needs, we categorised infectious group into two sub-cases: Mild [M] and Critical [C]; where Mild cases did not require hospital beds; Critical cases need hospital beds but possibly cannot get it due to shortage of health sources. Conceptually, the modified modal is shown in Figure.1.

This modal assumed that S is initial susceptible population of certain region; and incorporated an initial intervention of surveillance and isolation of cases in contain phase by a parameter $\beta$ [14-15]. If effectiveness of intervention in contain phase was not sufficiently strong, susceptible individuals may contract disease with a given rate when in contact with a portion of exposed population E. After an incubation period $\alpha_1$, the exposed individuals became the infectious population I at a ratio $1/\alpha_1$. The incubation period was assumed to be 6 days [8]. Once exposed to infection, infectious population started from Mild cases M to Critical cases C at a ratio $a$. Critical cases led to deaths at a ratio $d$; other infectious population finally recovered.
Using Wuhan’s data, our estimation was close to the practical trend of outbreaks in Wuhan, and gave similar results to other works [11]. We tested that transmission rate from I to S is about 0.157; transmission rate from E to S is about 0.787 [11]. The incubation period was assumed to be 6 days [8]. As for other parameters, we followed the COVID-19 official report from WHO [25], and gave a medium estimation on average durations related from infectious, to mild or critical case, and death or recovery were shown in Table 1.

</table>
Regarding the percentage of elderly people in the UK, it was assumed as 18%. The total number of NHS hospital beds was given as 167589 with an initial occupied ratio up to 85%. Considering that UK government began to release NHS hospital beds after COVID-19 breakouts, we assume the occupied ratio reduced to 80% and would further fall to 40% by April 04, 2020. Accounting for other serious disease cases requiring NHS hospital beds in the early breakout of COVID-19, we assumed that a ratio of available hospital beds for COVID-19 critical cases was initially at 80%, and gradually raised to 100%.

The intervention intensity was related to the population density and human mobility. We gave an initialization to London and non-London regions: (M=15, population: 9.3 million), non-London regions (M=14, population: 57.2 million). After taking any kind of interventions, we assumed the change of M would follow a reasonable decline or increase in 3-5 days.

If we assumed the overall population of a certain region is N, the number of days is t, the dynamic transmissions of each components of our model are defined as follow:

$$\frac{dS(t)}{dt} = -\frac{\beta_1 S(t)I(t)}{N} - \frac{\beta_2 S(t)E(t)}{N}$$  \hspace{1cm} (1)

$$\frac{dE(t)}{dt} = \frac{\beta_1 S(t)I(t)}{N} + \frac{\beta_2 S(t)E(t)}{N} - \alpha E(t) - \gamma_1 E(t)$$  \hspace{1cm} (2)

$$\frac{dI(t)}{dt} = \frac{\alpha E(t)}{N} + \frac{d(t)}{dt} = \frac{dM(t)}{dt} + \frac{dC(t)}{dt}$$  \hspace{1cm} (3)

$$\frac{dR(t)}{dt} = \gamma_1 E(t) + \gamma_2 M(t) + \gamma_3 C(t)$$  \hspace{1cm} (4)

Regarding Mild cases, Critical cases and Death, the dynamic transmission is as below:

$$\frac{dM(t)}{dt} = \alpha_1 E(t) - \alpha_2 \frac{c+s}{m} M(t) - \gamma_2 M(t)$$  \hspace{1cm} (5)

$$\frac{dC(t)}{dt} = \alpha_3 M(t) - \gamma_3 C(t) - \frac{d}{c+s} C(t)$$  \hspace{1cm} (6)

$$\frac{dD(t)}{dt} = d \frac{c}{c+s} C(t)$$  \hspace{1cm} (7)

### 2.2 Implementation of dynamic transmission

We need to estimate the defined parameters including $\alpha_1$, $\alpha_2$, $\beta$, and $\gamma_1$, $\gamma_2$, $\gamma_3$, $\beta$, where $\beta$ is the product of the people exposed to each day by confirmed infected people (k) and the probability of transmission (h) when exposed (i.e., $\beta = kh$) and $\gamma$ is the incubation rate which is the rate of latent individuals becoming symptomatic (average duration of incubation is $1/\alpha_1$). According to report [8], the incubation period of COVID-19 was reported to be between 2 to 14 days, we chose the midpoint of 6 days. $\gamma$ is the average rate of recovery or death in infected populations. Using epidemic data from [6], we used SEMCR model to determine the probability of transmission (b) which was used to derive $\beta$ and the probability of recovery or death ($\gamma$). The number of people who stay susceptible in each region was similar to that of its total resident population. Other parameters were estimated with early prediction of Hubei cases in [6] on January 23 2020 using Monte Carlo simulation, as shown in the Table.1

Here, $i$ is the efficiency of isolation contacts; $m$ is the proportion of mild case; $s$ is the proportion of severe case, and parameter $c$ is the proportion of critical case. $O$ is the percentage of people over 65 in the UK.

$\beta_1$ is the transmission rate from I to S, $\beta_2$ is the transmission rate from E to S. $\phi_1$ is the transmission rate from E to M (1/\alpha_1 incubation period), $\phi_2$ is the transmission rate from M to C (1/\alpha_2 average period from M to C).

$\gamma_1$ is the transmission rate from E to R (1/\tau_1 average period from E to R), $\gamma_2$ is the transmission rate from M to R (1/\tau_2 average period from M to R), $\gamma_3$ is the transmission rate from NH to R (1/\tau_3 average period from NH to R), $\gamma_4$ is the transmission rate of older people from IH to R (1/\tau_4 average period of older people from IH to R), $\gamma_5$ is the transmission rate of non-older people from IH to R (1/\tau_5 average period of non-older people from IH to R).

$\delta_1$ is the transmission rate from NH to R (1/\delta_1 average period from NH to D), parameter $\delta_2$ is the transmission rate of older people from IH to R (1/\delta_2 average period of older people from IH to D), $\delta_3$ is the transmission rate of non-older people from IH to R (1/\delta_3 average period of non-older people from IH to D).

$B_t$ is the number of hospital beds in the UK, $J_t$ is the percentage of occupied hospital beds for COVID-19 critical cases, $H_t$ is the percentage of unoccupied hospital beds, $M_t$ is the intensity of intervention.

Notably, as for the strength of intervention M, it was related to the population density in a region. We used a benchmark reported in [11] that assumes Hubei province with no intervention as M = 15, and after suppression intervention, M reduced to 3. When applying our model to other cases, M was initialized according to the population density and human mobility in these places. Also, after taking any kind of interventions, the change of M would follow a reasonable decline or increase over few days, not immediately occur at the second day. The implementation of dynamic transmission of SEMCR model follows steps as below:

$$S_{t+1} = S_t - \frac{\beta_1 M_t S_t}{N_t} - \frac{\phi_1 M_t S_t}{N_t}$$  \hspace{1cm} (8)

$$E_{t+1} = E_t + \frac{\beta_1 M_t S_t}{N_t} + \frac{\phi_2 M_t S_t}{N_t} - \phi_1 E_t - \gamma_1 E_t$$  \hspace{1cm} (9)

$$M_{t+1} = M_t + \phi_1 E_t - \phi_2 (\frac{c+s}{m}) M_t - \gamma_2 M_t$$  \hspace{1cm} (10)

$$\text{If } C_t > B_t J_t H_t :$$

$$NH_t = C_t - B_t J_t H_t$$  \hspace{1cm} (11)

$$IH_t = B_t J_t H_t$$  \hspace{1cm} (12)

$$\text{else}$$

$$NH_t = 0$$  \hspace{1cm} (13)

$$IH_t = C_t$$  \hspace{1cm} (14)
Figure 2: Illustration of controlling COVID-19 outbreaks in London and non-London regions by taking suppression and mitigation with parameters (a) London population: 9.30 million; non-London population: 57.2 million. (b) Suppression Intervention (M = 3), Mitigation Intervention: Low (M = 10). Moderate (M = 8). High (M = 6). (c) Effectiveness of isolation in contact phase (before 12th March 2020): London. 91%, non-London: 78%.

\]

\[-\delta_1 \left( \frac{c}{s + c} \right) n_h - \delta_2 \left( \frac{c}{s + c} \right) o_i h_t - \delta_3 \left( \frac{c}{s + c} \right) (1 - o) i h_t \tag{15}\]

\[i_{t+1} = m_{t+1} + c_{t+1} \tag{16}\]

\[d_{t+1} = d_t + \delta_1 \left( \frac{c}{s + c} \right) n_h + \delta_2 \left( \frac{c}{s + c} \right) o_i h_t + \delta_3 \left( \frac{c}{s + c} \right) (1 - o) i h_t \tag{17}\]

\[r_{t+1} = r_t + \gamma_1 e_t + \gamma_2 m_t + \gamma_3 n_h + \gamma_4 o_i h_t + \gamma_5 (1 - o) h_t \tag{18}\]

3 EXPERIMENTS

3.1 Effectiveness of suppression

We estimated that suppression with intensity M = 3 was taken in both London and non-London regions in the UK on the 46th day (March 23rd, 2020). The model reproduced the observed temporal trend of cases within London, non-London and the UK. As shown in Figure 2, it captured the exponential growth in infections between the 35th day (March 12th, 2020) and the 55th day (April 1st, 2020). We estimated that at the day (on March 23rd, 2020) to take intervention, daily infectious population (Exposed) in the UK actually reached 157950. Our results suggested there were nearly 26 times more infections in the UK than were reported as confirmed cases (6030 on March 23rd, 2020). The infections in London nearly occupied about 23% of the overall UK infections. 12th, 2020, M in the UK was adjusted to 12 from March 12th 2020 to March 23rd 2020.
But after taking intensive suppression on 23\textsuperscript{rd} March in the UK, daily exposed and infectious population were greatly reduced. A rapid decline in $R$ has occurred in later March, from $2.61[1.32-4.32]$ at the 24\textsuperscript{th} day (1\textsuperscript{st} March 2020) to $0.69[0.59-0.79]$ at the 51\textsuperscript{st} day (28\textsuperscript{th} March 2020). It implied implementing suppression in the UK performed significantly impact on reduction of infections. In Fig.2, we also estimated that the peak of infection in the UK would have occurred between 29\textsuperscript{th} March and 3\textsuperscript{rd} April 2020; the peak of death would have occurred between 18\textsuperscript{th} April and 24\textsuperscript{th} April 2020.

The results in the UK appeared a similar trend as Wuhan in Fig.2, where daily exposed and infectious population were greatly reduced. The total deaths by the 200\textsuperscript{th} day (August 24\textsuperscript{th}, 2020) in the UK was about 69511, where London had about 12921 deaths and non-London regions had about 56590 deaths. The outbreak of COVID-19 could be possibly controlled by the 100\textsuperscript{th} day (May 16\textsuperscript{th} 2020), and can be nearly ended by the 150\textsuperscript{th} day (July 5\textsuperscript{th} 2020). The difference was that the peak of daily infectious population ($E = 50200$) of London was nearly 3.4 times greater than the one in Wuhan ($E = 32880$); the peak time (the 50\textsuperscript{th} day) of daily infections in London was 18 days later than the one (the 32\textsuperscript{nd} day) in Wuhan. It was probably because suppression applied in Wuhan (the 32\textsuperscript{nd} day) was 14 days earlier than London (the 46\textsuperscript{th} day). It implied that earlier suppression could reduce infections significantly, but may lead to an earlier peak time of healthcare demand.
3.2 Effectiveness of mitigation
We simulated that mitigation with low, moderate and high intensity (M = 6, 8, 10) were taken in both London and non-London regions in the UK at the 46th day (March 23rd, 2020), as show in Fig.2. Considering that the UK went to delay phase on the 35th day (March 12th, 2020), M in the UK was adjusted to 12 from March 12th 2020 to March 23rd 2020.

The simulated results showed that mitigation strategies were able to delay the peak of COVID-19 breakouts in the UK but ineffective to reduce total infectious populations. Compared to suppression, mitigation taken in the UK gave a slower decline in R in March, from 2.73[0.97-5.40] on the 24th day (1st March 2020) to 0.98[95% CI 0.88-1.09] on the 110th day (27th May 2020). It implied that during this period, there were still much growth of infections in the UK. But London had lower R than non-London regions.

We estimated that the peak of daily infectious population was reduced to 3.6 million (M = 10) to 1.9 million (M = 8) or 0.69 million (M = 6); the peak date of daily infections was about on the 80th, 92nd and 110th day. Compared to suppression, the total deaths in the UK increased to 2.8 million (M = 10) to 2.1 million (M = 8) or 1.1 million (M = 6), where London had about 0.38 million (M = 10) to 0.28 million (M = 8) or 0.15 million (M = 6) and non-London regions had about 2.4 million (M = 10) to 1.8 million (M = 8) or 1 million (M = 6). The periods of breakouts with varied mitigations were extended to 160, 200 or 300 days.

3.3 Effectiveness of multiple interventions
We simulated two possible situations in London and the UK by implementing rolling interventions as shown in Figure 3. We assumed that all regions in the UK implemented an initial 3 weeks suppression intervention (M=3) from the 46th day (March 23rd 2020) to the 67th day (April 13th 2020). Then, two possible rolling interventions were given: 1) to keep suppression in London, and take a 3 weeks rolling intervention between suppression and high intensity mitigation (M = 5) in non-London regions; (2) to take a 3 weeks rolling intervention between suppression and high intensity mitigation (M = 5) in all UK.

The simulated results showed the epidemic appeared a unimodal distribution trend over 350 days, longer than the period of suppression. Similar to suppression in Figure 3, the peak date of infectious population in London or non-London regions remain same at the 50th day. After three weeks, rolling intervention with released intensity in non-London regions led to a fluctuation with 4 or 5 peaks of infections until the end of epidemic. The total deaths in the UK were greatly reduced to a range from 143 thousand to 154 thousand. It was about 85%-100% more than the outcome of taking suppression in all the UK.

Above two rolling interventions taken in the UK gave a similar trend of R as suppression, where there was a fast decline in R in March, from 2.61[1.32-4.32] on the 24th day (1st March 2020) to 0.69[0.59-0.79] on the 51st day (28th March 2020). It implied that 3 weeks rolling intervention (M = 3 or 5) had equivalent effects on controlling transmissions as suppression, but need to be maintained in a longer period of 350 days. From then, R value was oscillated between 1.22 [1.04-1.41] and 0.77 [0.63-0.92] with the shrinkage of intervention intensity.

3.4 Optimal rolling intervention
We simulated other possible rolling interventions with varied period (2, 3 and 4 weeks) and intensity (M = 4, 5 and 6). The results first revealed that rolling intervention with middle intensity (M = 6) cannot control the outbreaks in one year, where the distribution of epidemic was a multimodal trend as similar to mitigation outcomes in Figure 3. The overall infections and deaths significantly increased to over 14 million and 319 thousand. While the peak time of healthcare demand for severe critical cases delayed to the 112th – 139th day, the total deaths of the UK would be double than other rolling interventions with low intensity.

Another finding was that given equivalent intensity (M= 3 or 5) of rolling interventions, the longer period (4 weeks) led to slight reduction of the total deaths to 151164, compared to 154569 of 3 weeks rolling and 160236 of 2 weeks rolling in the UK. The peak time of healthcare demand nearly occurred at same: the 84th-111st day; with an equivalent peak value. Thus, in balance of total deaths and human mobility restriction, 3 weeks of period might be a feasible choice.

We considered the length of intervention in the UK impacting on social and economic. Maintaining a period of suppression in London, it was possible to control the outbreaks at the 100th-150th day that minimized economic loss to the greatest extent. Due to lower population density and less human mobility of non-London regions, 3 weeks rolling intervention was appropriated to non-London regions for balancing the total infections and economic loss, but the length of this strategy was extended to 300 days.

4. DISCUSSION
Notably, the total infections estimated in our model was measured by Exposed population (asymptomatic), which might be largely greater than other works only estimating Infectious population (symptomatic). We found that a large portion of self-recovered population were asymptomatic or mild symptomatic in the COVID-19 breakouts in Wuhan (occupied about 42%-60% of the total infectious population). These people might think they had been healthy at home because they did not go to hospital for COVID-19 tests. It was one important issue that some SEIR model predicted infectious population in Wuhan that 10 times over than confirmed cases [12-13]. Early release of intensity might increase a risk of the second breakout.

There are some limitations to our model and analysis. First, our model’s prediction depends on an estimation of intervention intensity that is presented by average-number contacts with susceptible individuals as infectious individuals in a certain region. We assumed that each intervention had equivalent or similar effect on the reproduction number in different regions over time. The practical effectiveness of implementing intervention intensity might be varied with respect to cultures or other issues of certain county. In the UK or similar countries, how to quantify intervention intensity needs an accurate measure of combination of social distancing of the entire population, home isolation of cases and household quarantine of their family members. As for implementing rolling interventions in the UK, the policy needs to
be very specific and well-estimated at each day according to the number of confirmed cases, deaths, morality ratio, health resources, etc.

Secondly, our model used a variety of plausible biological parameters for COVID-19 based on current evidence as shown in Table 1, but these assumed values might be varied by populations or countries. For instance, we assumed that average period of mild cases to critical cases is 7 days, and average period of elderly people in hospital from severe cases to deaths was 14 days, etc. The change of these variables may impact on our estimation of infections and deaths in the UK.

Lastly, our model assumes a condition that there will be a reasonable growth of available hospital source as time goes in the UK after 23rd March 2020. This was actually supported by latest news that Nightingale hospital that enables holding 4000 patients opened at London Excel centre on 4th April 2020. Our results show that taking rolling intervention is one optimal strategy to effectively and efficiently control COVID-19 outbreaks in the UK. This strategy potentially reduces the overall infections and deaths; delays and reduces peak healthcare demand. In future, our model will be extended to investigate how to optimise the timing and strength of intervention to reduce COVID-19 morality and specific healthcare demand.

5 CONCLUSION
This paper conducts a feasibility study by defining a mathematical model named SEMCR that analyses and compares mitigation and suppression intervention strategies for controlling COVID-19 outbreaks in London and Wuhan Cases. The model was fitted and evaluated with public dataset containing daily number of confirmed active cases including Wuhan, London and non-London regions in the UK. The experimental findings show that the optimal timing of interventions differs between suppression and mitigation strategies, as well as depending on the definition of optimal. In future, our model could be extended to investigate how to optimise the timing and strength of intervention to reduce COVID-19 morality and healthcare demand in more complex situations.
